When someone mentions the name of a known person we immediately recall her face and possibly many other traits. This is because we possess the so-called associative memory – the ability to correlate different memories to the same fact or event. Associative memory is such a fundamental and encompassing human ability (and not just human) that the network of neurons in our brain must perform it quite easily. The question is then whether electronic neural networks – electronic schemes that act somewhat similarly to human brains – can be built to perform this type of function. Although the field of neural networks has developed for many years, a key element, namely the synapses between adjacent neurons, has been lacking a satisfactory electronic representation. The reason for this is that a passive circuit element able to reproduce the synapse behaviour needs to remember its past dynamical history, store a continuous set of states, and be “plastic” according to the pre-synaptic and post-synaptic neuronal activity. Here we show that all this can be accomplished by a memory-resistor (*memristor* for short). In particular, by using simple and inexpensive off-the-shelf components we have built a memristor emulator which realizes all required synaptic properties. Most importantly, we have demonstrated experimentally the formation of associative memory in a simple neural network consisting of three electronic neurons connected by two memristor-emulator synapses. This experimental demonstration opens up new possibilities in the understanding of neural processes using memory devices, an important step

forward to reproduce complex learning, adaptive and spontaneous behaviour with electronic neural networks.

One of the most important functions of the human brain is the ability to associate different memories to specific events [1]. This fundamental property is not just limited to humans but it is shared by many species in the animal kingdom. Arguably the most famous example of this are experiments conducted on dogs by Pavlov [2] whereby salivation of the dog's mouth is first set by the sight of food. Then, if the sight of food is accompanied by a sound (e.g., the tone of a bell) over a certain period of time, the dog learns to associate the sound to the food, and salivation can be triggered by the sound alone, without the intervention of vision.

Since associative memory can be induced in animals and we, humans, use it extensively in our daily lives, the network of neurons in our brains must execute it very easily. It is then natural to think that such behaviour can be reproduced in artificial neural networks as well - a first important step in obtaining artificial intelligence. The idea is indeed not novel and models of neural networks have been suggested over the years that could theoretically perform such function [3-5]. However, their experimental realization, especially in the electronic domain, has remained somewhat difficult. The reason is that an electronic circuit that simulates a neural network capable of associative memory needs two important components: neurons and synapses, namely connections between neurons. Ideally, both components should be of nanoscale dimensions and dissipate little energy so that a scale-up of such circuit to the number density of a typical human brain (consisting of about 10^{10} synapses/cm²) could be feasible. While one could envision an electronic version of the first component relatively easily, an electronic synapse is not so straightforward to make. The reason is that the latter needs to be flexible ("plastic") according to the type of signal it receives, its strength has to depend

on the dynamical history of the system, and it needs to store a continuous set of values (analog element).

In the present paper, we experimentally show that a resistor with memory (*memristor* for short [6,7]) could indeed function as a synapse. Memristors belong to the larger class of memory-circuit elements (which includes also memcapacitors and meminductors) [8], namely circuit elements whose response depends on the whole dynamical history of the system. Memristors can be realized in many ways, ranging from oxide thin films [9-11] to spin memristive systems [12]. However, all these realizations are limited to the specific material or physical property responsible for memory, and as such they do not easily allow for tuning of the parameters necessary to implement the different functionalities of electronic neural networks.

In order to overcome these difficulties we have developed flexible electronic versions of neurons and synapses whose behavior can be easily tuned to the functions found in biological neural cells. Of equal importance, the electronic neurons and synapses were fabricated using inexpensive off-the-shelf electronic components resulting in few dollars cost for each element, and therefore can be realized in any undergraduate (or even high-school) electronic laboratory. Clearly, we do not expect that with such elements one can scale up the resulting electronic neural networks to the actual brain density. However, due to their simplicity reasonably complex neural networks can be constructed from the two elemental blocks developed here and we thus expect several functionalities could be realized and studied.

For the purpose of this paper we have built the neural network shown in Fig. 1. We have then shown that such circuit is capable of *associative memory*. In this network, two input neurons N_1 and N_2 are connected with an output neuron N_3 by means of synapses S_1 and S_2 . As an example of the functionality that this network can provide,

we can think about the animal memory we have described above [2] in which the first input neuron (presumably located in the visual cortex) activates under a specific visual event, such as “sight of food”, and the second input neuron (presumably located in the auditory cortex) activates under an external auditory event, such as a particular “sound”. Depending on previous training, each of these events can trigger “salivation” (firing of the third output neuron). If, at a certain moment of time, only the “sight of food” leads to “salivation,” and subsequently the circuit is subjected to both input events, then, after a sufficient number of simultaneous input events the circuit starts associating the “sound” with the “sight of food”, and eventually begins to “salivate” upon the activation of the “sound” only. This process of learning is a realization of the famous Hebbian rule stating, in a simplified form, that “neurons that fire together, wire together”.

Electronic neuron. Biological neurons deal with two types of electrical signals: receptor (or synaptic) potentials and action potentials. A stimulus to a receptor causes receptor potentials whose amplitude is determined by the stimulus strength. When a receptor potential exceeding a threshold value reaches a neuron, the latter starts emitting action potential pulses, whose amplitude is constant but their frequency depends on the stimulus strength. The action potentials are mainly generated along axons in the forward direction. However, there is also a back-propagating part of the signal [13,14] which is now believed to be responsible for synaptic modifications (or learning) [14,15].

We have implemented the above behaviour in our electronic scheme as shown in Fig. 2a using an analog-to-digital converter and a microcontroller. The input voltage is constantly monitored and once it exceeds a threshold voltage, both forward and backward pulses are generated whose amplitude is constant (we set it here for convenience at 2.5V), but pulse separation varies according to the amplitude of the input signal. In Fig. 2b we show the response of the electronic neuron when three resistors of different values are subsequently connected between the input of the neuron

and 2.5V. When the resulting voltage (determined by the external resistor and internal resistor connected to the ground in Fig. 2a) is below the threshold voltage ($t < 1s$ in Fig. 2b), no “firing” occurs (no change in the output voltage). When the input voltage exceeds the threshold ($t > 1s$ in Fig. 2b), the electronic neuron sends forward and back-propagating pulses. The pulse separation decreases with increase of the input voltage amplitude as it is evident in Fig. 2b.

Electronic synapse. As electronic synapse we have built a *memristor emulator*, namely an electronic scheme which simulates the behaviour of *any* memory-resistor. In fact, our memristor emulator can reproduce the behaviour of any voltage- or current-controlled memristive system. The latter is described by the following relations

$$y(t) = g(x, u, t) u(t) \quad (1)$$

$$\dot{x} = f(x, u, t) \quad (2)$$

where $y(t)$ and $u(t)$ are input and output variables, such as voltage and current, $g(x, u, t)$ is a generalized response (memresistance R , or memductance G), x is a n -dimensional vector describing the internal state of the device, and $f(x, u, t)$ is a continuous n -dimensional vector function [7, 8].

As Fig. 2a illustrates schematically, our memristor emulator consists of the following units: a digital potentiometer, an analog-to-digital converter and a microcontroller. The A (or B) terminal and the Wiper of the digital potentiometer serve as the external connections of the memristor emulator. The resistance of the digital potentiometer is determined by a code written into it by the microcontroller. The code is calculated by the microcontroller according to Eqs. (1) and (2). The analog-to-digital converter provides the value of voltage applied to the memristor emulator needed for the digital potentiometer code calculation. The applied voltage can be later converted to

the current since the microcontroller knows the value of the digital potentiometer resistance.

In our experiments, we implemented a threshold model of voltage-controlled memristor previously suggested in our earlier paper [16] and also discussed in Ref. [8]. In this model, the following equations (which are a particular case of Eqs. (1,2)) were used:

$$G = x^{-1}, \quad (3)$$

$$\dot{x} = (\beta V_M + 0.5(\alpha - \beta)[|V_M + V_T| - |V_M - V_T|])(\theta(V_M)\theta(x - R_1) + \theta(-V_M)\theta(R_2 - x)), \quad (4)$$

where $\theta(\cdot)$ is the step function, α and β characterize the rate of memristance change at $|V_M| \leq V_T$ and $|V_M| > V_T$, respectively, V_M is a voltage drop on memristor, V_T is a threshold voltage and R_1 and R_2 are limiting values of memristance. In simple words, the memristance changes between R_1 and R_2 with different rates below and above the threshold voltage. This activation-type model was inspired by recent experimental results on thin-film memristors [10] and as we discuss later it reproduces synapse plasticity.

To test that our emulator does indeed behave as a memristor, we have used the circuit shown in the inset of Fig. 3b, in which an ac voltage is applied to the memristor emulator, R , connected in series with a resistor R_0 which was used to determine the current. The obtained current-voltage (I-V) curves, presented in Fig. 2b, demonstrate typical features of memristive systems. For instance, all curves are pinched hysteresis loops passing through (0,0) demonstrating no energy storage property [7,8] of memristive systems. Moreover, the frequency dependence of the curve is also typical for memristive systems: the hysteresis shrinks at low frequencies, when the system has

enough time to adjust its state to varying voltage, and at higher frequencies, when the characteristic timescale of system variables change is longer than the period of voltage oscillations.

Associative memory. Using the electronic neurons and electronic synapses described above, we have built an electronic scheme corresponding to the neural network depicted in Fig. 1. In this scheme, we directly connect the memristor terminals to the third neuron input, although different connection schemes, e.g., using a capacitor, are possible. Fig. 4 demonstrates the associative memory development in such a network. Our experiment consists in application of stimulus signals to the first (“sight of food”) and second (“sound”) neurons, and monitoring of the output signal on the third (“salivation”) neuron. We start from a state when the first synaptic connection is strong (low resistance state of the first memristor) and second synaptic connection is weak (high resistance state of the second memristor).

In the first “probing phase” ($t < 9s$, Fig. 4) we apply separate non-overlapping stimulus signals to the “sight of food” and “sound” neurons. This results in the “salivation” neuron firing when a stimulus signal is applied to the “sight of food” neuron, but not firing when a stimulus signal is applied to the “sound” neuron. Electronically, it occurs because pulses generated by the “sight of food” neuron exceed the threshold voltage of the “salivation” neuron (due to a low resistance of the first memristor synapse) while the voltage on the “salivation” neuron input due to the “sound” neuron pulses is below the threshold voltage of the “salivation” neuron. In this phase there is no memristor state change since the first memristor is already in its limiting state (with minimal resistance allowed) and its resistance cannot decrease further, and voltage drop on the second memristor is below its voltage threshold.

In the “learning phase” ($9s < t < 12s$, Fig. 4), stimulus voltages are applied simultaneously to both input neurons, thus generating trains of pulses. The pulses from different neurons are uncorrelated, but sometimes they do overlap, owing to a random component in the pulse separation (see Fig. 2 caption for details). During this phase, in some moments of time, back-propagating pulses from the “salivation” neuron (due to excitation from the “sight of food” neuron) overlap with forward propagating pulses from the “sound” neuron causing a high voltage across the second memristor synapse. As this voltage exceeds the memristor threshold, the second synapse state changes and it switches into a low resistance state. It is important to note that this change is possible when both stimuli are applied together (in other words they correlate). As a result, an association between input stimuli develops and the circuit “learns” to associate the “sight of food” signal to the “sound” signal.

Our measurements during the second probing phase ($t > 12s$, Fig. 4) clearly demonstrate the developed association. It is clear that, in this phase, *any* type of stimulus - whether from the “sight of food” or from the “sound” neurons - results in the “salivation” neuron firing.

Summary. We have thus shown that the electronic (memristive) synapses and neurons we have built both satisfy the functionalities of their biological counterparts, and when combined together in networks - specifically the one represented in Fig. 1 of this work – they give rise to an important function of the brain, namely associative memory. It is worth again mentioning that, although other memristors (e.g., those built from oxide thin films [17]) could replace the emulator we have built, the electronic neurons and synapses proposed here are electronic schemes that can be built from off-the-shelf inexpensive components. Together with their extreme flexibility in representing essentially any programmable set of operations, they are ideal to study much more complex neural networks [18] that could adapt to incoming signals and take decisions based on

correlations between different memories, as we humans do on a regular basis in our daily lives. This opens up a whole new set of possibilities in reproducing different types of learning and possibly even more complex neural processes.

Figure 1 | Artificial neural network for associative memory. Real neurons and their networks are very complex systems whose behaviour is not yet fully understood. However, some simple brain functions can be elucidated studying significantly simplified structures. Here, we consider three neurons (N_1 , N_2 and N_3) coupled by two synapses (S_1 and S_2). The output signal is determined by input signals and strengths of synaptic connections which can be modified when learning takes place.

Figure 2 | Electronic neuron. a, Main components of the electronic neuron proposed here are an analog-to-digital converter (ADC) and a microcontroller. NC means “not connected”. If the voltage value V_{in} on the input terminal (I) exceeds a threshold voltage V_{th} (in our experiments $V_{th} = 1.5$ V), the microcontroller connects the input pin to -2.5V and output pin (O) to 2.5V for 10 ms, thus sending forward and backward pulses. After that, it waits for a certain amount of time δt and everything repeats again. If $V_{in} < V_{th}$, then the microcontroller just continuously samples V_{in} . The waiting time was selected as $\delta t = \tau - \gamma \cdot (V_{in} - V_{th}) + \lambda(\eta - 0.5)$, where $\tau = 60$ ms, $\gamma = 50$ ms/V, $\lambda = 10$ ms and η is a random number between 0 and 1. In our experimental realization, we used microcontroller dsPIC30F2011 from Microchip with internal 12bits ADC and a possibility of pin multiplexing, so that the only additional elements were two 10k Ω resistors. Actual measurements were done using 5V voltage span, with further assignment of the middle level as zero. **b,** Response of the electronic neuron on input voltages of different magnitude, the red dashed line is the threshold voltage and is only a guide to the eye. When $V_{in} < V_{th}$, no “firing” occurs. When $V_{in} > V_{th}$, the electronic neuron sends pulses, with the average pulse separation decreasing with increasing V_{in} . V_{out} is shifted for clarity.

Figure 3 | Electronic synapse. a, Schematic of the main units of the memristor emulator. The memristor emulator consists of a digital potentiometer, ADC and microcontroller. The digital potentiometer unit represents an element whose resistance is defined by a digital code written in it. Two terminals of this unit (A and W) are the external connection terminals of the memristor emulator. The differential ADC converts the voltage between A and W terminals of the digital potentiometer into a digital value. The microcontroller reads the digital code from ADC and generates (and writes) a code for the digital potentiometer according to predefined functions $g(x,u,t)$ and $f(x,u,t)$ and Eqs. (1-2). These operations are performed continuously. In our circuit, we used a 256 positions 10k Ω digital potentiometer AD5206 from Analog Device and microcontroller dsPIC30F2011 from Microchip with internal 12bits ADC (see Ref. 11 for additional information). **b,** Measurements of memristor emulator response when $V(t) = V_0 \cos(2\pi\omega t)$ with $V_0 \approx 2\text{ V}$ amplitude is applied to the circuit shown in the inset with $R_0 = 10\text{ k}\Omega$. The following parameters determining the memristor emulator response (see Eqs. (3,4)) were used: $\alpha = \beta = 146\text{ k}\Omega/(\text{V}\cdot\text{s})$, $R_1 = 675\text{ }\Omega$, $R_2 = 10\text{ k}\Omega$. The signals were recorded using a custom data acquisition system.

Figure 4 | Development of associative memory. a, Using electronic neurons and electronic synapses (memristor emulators), we have built an electronic circuit corresponding to the neural network shown in Fig. 1. We have used the following parameters defining the operation of memristor emulators: $V_{th} = 4\text{ V}$, $\alpha = 0$, $\beta = 15\text{ k}\Omega/(\text{V}\cdot\text{s})$. At the initial moment of time, the resistance of S_1 was selected equal to $R_1 = 675\text{ }\Omega$ (lowest resistance state of memristor) and the resistance of S_2 was selected equal to $R_2 = 10\text{ k}\Omega$ (highest resistance state of

memristor). Correspondingly, in the first probing phase, when Input 1 and Input 2 signals are applied without overlapping, the output signal develops only when Input 1 signal is applied. In the learning phase (see also **b** for more detailed picture), Input 1 and Input 2 signals are applied simultaneously. According to Hebbian rule, simultaneous firing of input neurons leads to development of a connection, which, in our case, is a transition of the second synapse S_2 from high- to low-resistance state. This transition is clearly seen as a growth of certain pulses in the signal $V_{3,in}$ (voltage at the input of third neuron) in the time interval from 10.25s to 11s in **b**. In the subsequent probing phase, we observe that “firing” of *any* input neuron results in the “firing” of output neuron, and thus an associative memory realization has been achieved. The curves in **a** and **b** were displaced for clarity.
